Abstract

Purpose: To evaluate the variations of intraocular pressure (IOP), morphometric papillary characteristics, perimetric indices, and electrophysiological parameters, i.e., pattern electroretinogram (PERG) and visual evoked potentials (VEPs), before and after topical hypotonization therapy in normal-tension glaucoma (NTG) suspects.

Methods: We evaluated 38 eyes of 20 patients with intraocular pressure of < 21 mmHg (measured with Goldmann applanation tonometry), initial glaucomatous optic neuropathy (assessed with Heidelberg Retina Tomograph (HRT): retinal fiber layer (RNFL) and/or linear cup/disk (linear C/D), minimal visual defects (Octopus 101: G2 program), visual acuity of more than 15/20 with best correction, and pathological electrophysiological parameters (valued with pattern electroretinogram and visual evoked potentials), free of systemic or other ocular diseases. All parameters were evaluated at the beginning of the study (T₀) and after 12 months from the start of the therapy (T₁₂). A randomized normal control group (27 eyes of 14 subjects) with apparent larger disc cupping underwent all exams at the start of the study and after 12 months.

Results: Among electrophysiological parameters, at the beginning of the study P100 VEPs latency was slightly increased and P100 amplitude was reduced in NTG compared to normal subjects, with no significant variation after 12 months. P50 PERG latency was quite similar between the NTG and normal groups, and showed no modification after therapy. Compared to normal subjects, P50N95 complex
PERG amplitude in NTG was reduced and showed a slight increase after 12 months (1.8 vs 1.5; 2.4 vs 1.9 micronvolts, with different checkerboard spatial frequency). Cortical-retinal time (CRT) was slightly delayed in NTG and showed no modification after therapy. Among visual field indices, mean defect (MD) and corrected loss variance (CLV) were slightly higher in NTG, and showed no significant modification after therapy. Among morphometric optic nerve head characteristics, linear C/D and RNFL thickness were quite similar between the NTG and normal groups, and showed no modification after therapy. IOP was also similar between NTG and normal subjects, and decreased after therapy in the NTG group.

**Conclusion:** From the perspective of an integrated diagnostic, electrophysiological tests (VEPs and PERG) may provide a more sensitive measure of retinal ganglion cell (RGC) integrity and help to distinguish between normal-tension glaucoma suspects before perimetric alterations are evident, and normal subjects with apparent larger disc cupping.

**Keywords:** pattern electroretinogram (PERG), visual evoked potentials (VEPs), normal-tension glaucoma (NTG) suspects, minimal visual defects, initial glaucomatous optic neuropathy

### A short guide to read electrophysiological parameters

**1. Pattern electroretinogram (PERG)**

The pattern electroretinogram (PERG) represents an objective and direct measure of retinal ganglion cell (RGC) function. It is a retinal biopotential evoked by a temporally modulated patterned stimulus (checkerboard or grating) of constant mean luminance. The PERG waveform depends on the temporal frequency of the stimulus. At low temporal frequencies (< 6 reversals per second (rps), equivalent to 3 Hz), transient PERGs are obtained: the PERG waveform in normal subjects usually consists of a small initial negative component with a peak time (i.e., latency) of 35 msec (N35), followed at 45-60 msec by a much larger positive component (P50), and a large negative component at about 95 msec (N95). In glaucoma analysis, P50N95 complex amplitude (in micronvolt) — calculated from P50 peak to N95 peak — and P50 implicit time (or latency) (in msec) are measured with different spatial frequencies: either with checkerboard subtending 30’ of arc of visual angle or 15’ (smaller).

**2. Visual evoked potentials (VEPs)**

Visual evoked potentials (VEPs) characterize the state of the whole visual pathway. The waveform of the VEPs evoked by contrast reversal of pattern stimuli depends on the temporal frequency of the stimulus. Considerations
Electrophysiological evaluation in normal-tension glaucoma suspects

are the same as those for PERG. At low temporal frequencies (< 6 reversals per second (rps), equivalent to 3 Hz), transient VEPs are obtained: VEPs waveforms consist of an initial negative component with a peak time of approximately 75 msec (N75), followed by a larger positive component (P100) at 100-110 msec, and by a large negative component at 120-140 msec (N135). P100 latency (in msec) and amplitude (in micronvolt) are measured with different spatial frequencies: either with checkerboard subtending 30’ of arc of visual angle or 15’ (smaller).

Cortical-retinal time (CRT) is an electrophysiological index that analyzes neural conduction in post-retinal visual pathways; it is derived from simultaneous recordings of VEPs and PERGs and represents the latency difference between P50 PERG and P100 VEPs.

1. Introduction

Glaucoma is a multifactorial optic neuropathy characterized by progressive loss of retinal ganglion cells (RGC), changes in optic disk morphology, and visual field defects. Intraocular pressure (IOP) is a recognized risk factor for the development and progression of glaucomatous damage: multicenter studies have found that a 1 mmHg reduction decreased the risk of damage progression by 10%, and that conversion from ocular hypertension to manifest glaucoma is decreased by reducing IOP.1,2 A particular type of open-angle glaucoma, normal-tension glaucoma (NTG), has a typical glaucomatous optic neuropathy evolution with untreated IOP below 21 mmHg.3-5 Several population studies have suggested an incidence of NTG between 20% and 40% for all open-angle glaucomas.6,7 IOP is recognized as the most important risk factor for the development or progression of glaucomatous damage, even if pressure reduction does not necessarily slow or halt disease progression.8,9 In fact, in NTG other IOP-independent factors concur to the progression of the disease, including migraine, disk haemorrhage, occlusive vascular diseases, abnormal ocular blood flow, systemic hypotension, and sleep apnoea,10-12 even if there still are individual responses between diagnostic exams. Specifically, patients with NTG show a greater reduction in nocturnal blood pressure compared to healthy subjects, which is correlated to a more rapid progression of glaucoma.13-15

In addition to damaging RGC, glaucoma can also damage the post-retinal mechanism at the level of the lateral geniculate nucleus (LGN) of the thalamus and the primary visual cortex (V1).16 Hence, glaucoma can be associated with profound degenerative effects in the visual brain. Studies on experimental glaucoma in primates show neural degeneration of the LGN17-20 and activity changes in the visual cortex.19 Degeneration of the LGN and visual cortex has also been demonstrated in human glaucoma.16
Among diagnostic exams for glaucoma, the pattern electroretinogram (PERG) stands as a direct indicator of RGC function.\textsuperscript{21,22} PERG amplitude decreases with increasing age in normal subjects, which may be due to neural loss as well as to reduced retinal illuminance resulting from retinal miosis and reduced image contrast due to cataract or other opacities of optical media; therefore, response must be normalized for age.\textsuperscript{23,24}

PERG reflects ganglion-diffuse rather than focal damage,\textsuperscript{25,26} so correlations between altered PERGs and visual fields are not necessarily found.\textsuperscript{27,28} RGC loss above 30\% is associated with statistically significant changes in visual field sensitivity\textsuperscript{29}, so the visual field is not impaired in ocular hypertension or early manifest glaucoma.\textsuperscript{30}

Caprioli identified two distinct types of glaucoma field defects: a more diffuse loss of visual field sensitivity, correlated to IOP, and a less pressure-dependent, localized type. The first type may be due to diffuse dysfunction leading to progressive concentric enlargement of the optic nerve cup; as it is a mass response reflecting diffuse RGC dysfunction, PERG is often impaired in this type of glaucoma.\textsuperscript{31} Caprioli believes that the second type, \textit{i.e.}, glaucoma with focal visual field defects, is more correlated with vascular factors. In this type of glaucoma, PERG may still be normal until the majority of RGC are affected.\textsuperscript{32}

PERG is altered in glaucoma as well as in many cases of ocular hypertension (OHT).\textsuperscript{33-36} Several authors who have performed human studies find PERG to be a predictive value to identify those patients with elevated IOP who develop glaucoma before visual field changes occur;\textsuperscript{37-40} given that none of the eyes with initially normal PERG develop glaucomatous field defects;\textsuperscript{41} moreover Philippin, in a ten-year longitudinal study, found that 8\% of eyes develop manifest glaucoma (defined by visual field defect) with high sensitivity and specificity.\textsuperscript{40,42} In experimental glaucoma studies in monkeys, Marx found a reduction of PERG amplitude without evidence of cupping;\textsuperscript{43} in mice, Saleh and Porciatti show a progressive reduction of inner retina function with retinal fiber layer (RNFL) relatively spared: PERG amplitude reaches the noise level in many eyes when RNFL thickness decreases by 50\%.\textsuperscript{44,45}

Some authors have emphasized the correlation between PERG and progress of vertical cup-to-disc ratio,\textsuperscript{46} optic disk RNFL thickness loss measured by optical coherence tomography (OCT),\textsuperscript{47,48} and cup shape measure of the Heidelberg Retina Tomograph (HRT).\textsuperscript{49,50}

PERG has a higher sensibility to detect glaucomatous defects\textsuperscript{29,51,40} and is abnormal in most patients with manifest disease.\textsuperscript{49,52,47,51} PERG impairment always precedes visual field defects.\textsuperscript{53} As it reflects diffuse ganglion damage, there is a strong correlation between PERG and mean defect (MD) visual field index and a weak correlation with correct pattern standard deviation (CPSD) or corrected loss variance (CLV), both of which analyze local defects.\textsuperscript{48,53} There is no linear relationship between P50N95 amplitude and visual field loss and, in some cases, PERG changes can precede detectable field loss because PERG is particularly sensitive to early damage.\textsuperscript{54}
Electrophysiological evaluation in normal-tension glaucoma suspects

As referred above, PERG reflects the total amount of electrophysiological activity of RGC, i.e., represents an objective and direct measure of RGC function. Analysing the structure-function relationship in experimental and human studies, Marx,\textsuperscript{46} Ventura,\textsuperscript{55} and North\textsuperscript{56} suggested the hypothesis that there may be a stage of reversible dysfunction prior to RGC death. This period of dysfunction may happen long before ganglion cell loss. In glaucoma suspects or in early glaucoma, a reduction in PERG amplitude may be due to early RGC dysfunction. This dysfunction is potentially reversible and may be restored after IOP reduction.\textsuperscript{55} This improvement occurred not only in ocular hypertension (OHT) or hypertensive glaucoma (primary open-angle glaucoma, POAG),\textsuperscript{46} but also in NTG.\textsuperscript{56} Particularly in early glaucoma, after lowering IOP Ventura found a positive change in slope steepness that may indicate that the progressive degradation of RGC function has slowed down.\textsuperscript{57} Compared to POAG, PERG improvements in NTG were associated with smaller reductions of IOP;\textsuperscript{55} perhaps RGC dysfunction in NTG occurs at a lower IOP and, in turn, PERG improvements occur after smaller IOP reductions. However, small improvements in eyes with advanced visual field defects may be explained by fewer quantities of surviving RGC in the advanced stages of NTG.

Visual evoked potentials (VEPs) characterize the state of the whole visual pathway. In glaucomatous patients, there is a delay of P100 latency and/or P100 amplitude reduction.\textsuperscript{58,59,51} Parisi found a high specificity of VEPs in identifying normal subjects.\textsuperscript{51} VEPs show reduced amplitude in OHT and manifest glaucoma.\textsuperscript{60} Cortical-retinal time (CRT) is an electrophysiological index that analyzes neural conduction in post-retinal visual pathways; it is derived from simultaneous recordings of VEPs and PERGs\textsuperscript{61} and represents the latency difference between P50 PERG and P100 VEPs. Cortical-retinal time is unchanged in OHT, but increases as the disease progresses,\textsuperscript{47} and is correlated with a reduction in PERG amplitude so that signal transmission is progressively slower (revealed by a greater increase of P100 latency). Moreover, there is a correlation with optic nerve fiber thinning, measured by OCT.\textsuperscript{47} VEPs reflect the activity of the later stages in the visual processing chain, and are less affected by glaucoma than PERG.

In this study, we tested the hypothesis that electrophysiological dysfunctions are present in NTG suspects with early structural damage and no perimetric defect. Additionally, any structural or functional variations were assessed twelve months after starting therapy.

2. Methods

The study was approved by the Hospital Medical Ethics Committee, and informed consent was obtained from the subjects following an explanation of the nature and possible consequences of the study. Healthy control subjects and early-stage glaucoma patients were recruited at the Sacco Hospital eye clinic in Milan, Italy.
2.1. Patients with suspected NTG
Twenty subjects (38 eyes) with suspected normal-tension glaucoma were recruited. All patients underwent a complete clinical examination including best-corrected visual acuity, Goldmann applanation tonometry, optic nerve head assessment by slit lamp binocular indirect ophthalmoscopy, scanning laser tomography (Heidelberg Retina Tomograph (HRT), Germany), perimetry (Octopus 101: G2 program for glaucoma; Interzeag, Schlieren, Switzerland), VEPs and PERG recording (Biomedica Mangoni, Pisa, Italy).

Inclusion criteria were:
1. visual acuity of more than 15/20 with best correction;
2. untreated IOP (measured with Goldmann applanation tonometry) on a diurnal pressure curve inferior to 21 mmHg;
3. initial glaucomatous optic neuropathy evaluated with HRT in conjunction with the following inclusion criteria: 1) one sector measurement labelled “borderline” or “outside of normal” at Moorfield Regression Analysis; 2) retinal nerve fibre layer (RNFL) less than 200; 3) linear cup-disk (linear C/D) more than 600;
4. alteration of electrophysiological parameters, namely, decreased P50N95 PERG complex amplitude or/and decreased VEPs P100 wave amplitude. Values differing by less than two standard deviations from the correct normative value for age were considered non-pathological;
5. visual field indices: mean defect (MD) and correct loss variance (CLV), considering values “borderline” or “1st Stage” according to Glaucoma Staging System 2 perimetric stadiation.62,63

Exclusion criteria were:
1. history of refractive surgery;
2. high myopia;
3. other ocular or systemic diseases;
4. patients already in therapy or with other ocular or systemic diseases.

2.2. Healthy subjects
An age-matched control group of 14 healthy subjects (27 eyes) with the same morphological alterations (RNFL less than 200 and linear cup-disk (linear C/D) more than 600) but normal PERG, VEPs, and visual field indices; no ophthalmic diseases and no family history of glaucoma.

We analyzed these two groups at the start of the study (T₀) and after 12 months (T₁₂). Glaucomatous patients underwent hypotonizing therapy with prostaglandin eye drops, one drop a day; the controls did not undergo therapy.

2.3. Electroretinography
Electrophysiological tests (VEPs and PERG) were recorded monocularly and simultaneously.
2.4. PERG technique
A small silver chloride skin (active and reference) electrode was positioned on the lower eyelids. A skin electrode at the midfrontal position (in Fpz scalp) served as ground. PERG were recorded simultaneously with VEPs, with 30-minute and 15-minute black-and-white checkerboard pattern stimulus, 45 cd/m² mean luminance, reversing two times per second (square wave reversal) or counter phased at 1 Hz (thus evoking transient responses) at 98% contrast between black-and-white squares. Signals were amplified (50000 times) and filtered (pass band 1-100 Hz). The stimuli were generated on a cathode-ray tube monitor subtending 24° at a viewing distance of 114 cm.

At low temporal frequencies (< 6 rps), transient PERGs were obtained. The PERG waveform consists of a small initial negative component with a peak time of approximately 35 ms (N35), followed at 45-60 ms by a larger positive component (P50). The following wave is a large negative component at 90-100 ms (N95). P50 peak time (or latency) and P50N95 complex amplitude (i.e., from the peak of P50 to the peak of N95) were measured.

2.5. Visual evoked potentials (VEPs) technique
The scalp electrodes were placed according to the International 10/20 System. The active electrode was placed on the scalp over the visual cortex at Oz with the reference electrode at Fz. A skin electrode at the midfrontal position (in Fpz scalp) served as ground electrode.

VEPs were recorded simultaneously with PERG, with 30-minute and 15-minute black-and-white checkerboard pattern stimulus with 45 cd/m² mean luminance, reversing two times per second (square wave reversal) or counter phased at 1 Hz (thus evoking transient responses) at 98% contrast between black and white squares. Signals were amplified (50000 times) and filtered (pass band 1-100 Hz). The stimuli were generated on a cathode-ray tube monitor subtending 24° at a viewing distance of 114 cm.

At low temporal frequencies (< 6 rps), the pattern-reversal VEP waveform consists of N75, P100, and N135 peaks. P100 peak time (or latency) and P100 amplitude were measured.

2.6. Perimetry and visual field criteria
Octopus 101: G2 program for glaucoma; Interzeag, Schlieren, Switzerland Glaucoma Staging System 2 (GSS2) perimetric stadiation was used, which considers visual field defects by analyzing perimetric indices: MD and CLV. We included in this study no defect or initial defects: “borderline” (MD between 2.5 and 3; CLV between 3 and 4) or “1st stage” (MD between 3 and 6; CLV between 4 and 6) in two consecutive visual fields.
2.7. HRT technique
The HRT is a confocal scanning laser imaging device for the analysis of glaucomatous optic disk topography. With Moorfield Regression Analysis (MRA) for each sector of the optic nerve head (ONH), patients were included with at least a “borderline” global rim area, i.e., at least one measure outside the norm between 95% and 99% confidence interval (CI), linear cup disc (linear C/D) more than 0.55, and mean retinal nerve fiber layer thickness (RNFL thickness) less than 200.

2.8. Statistics
The main aim of the statistical analysis was to describe and quantify the diagnostic parameters for two groups, NTG suspects and healthy subjects, respectively. The analysis was performed on a sample of 38 eyes of patients (n = 20) with suspected NTG, and 27 eyes of healthy subjects (n = 14). For each eye, the following variables were available, both at T₀ (start of the study) and T₁₂ (twelve months later), except for pachimetry, which was recorded only at T₀:

1. electrophysiological measurements: latency and amplitude of the P50 PERG wave and P100 VEP wave, with 30-minutes and 15-minutes checkerboard pattern stimulus;
2. visual field indices: mean defect (MD), correct loss variance (CLV);
3. morphometric parameters: RNFL thickness, linear C/D;
4. intraocular pressure (IOP);
5. pachimetry.

Furthermore, CRT was defined as the difference between P100 VEPs wave latency and P50 PERG wave latency.

The variables above were summarized using means and standard deviations. A multivariate descriptive analysis was performed, using principal component analysis (PCA) methods, in order to identify possible patterns of electrophysiological measurements and other parameters in the two groups (NTG and healthy subjects), and to evaluate the correlation among such features. A brief sketch of such methods is reported in the following box.

The strategy of analysis was the following one:

1. In a preliminary step, the assumption of linear correlation among the variables under examination was checked by examining correlation coefficients (Pearson’s r and Spearman’s rho) and scatterplots for each couple of variables.
2. Two separate PCAs were performed, for electrophysiological measurements and the remaining variables, respectively. In each one, measurements at T₀ of each variable were used as active variables. This allowed to focus attention on the relationships among the elements that could be potentially used for an early diagnosis. The association among measurements at T₀ and T₁₂ was evaluated by including the latter ones in the PCA as supplementary variables. The number of relevant principal components was determined.
by examining the scree-plot. Both variables and individuals (i.e., eyes) were represented through principal component biplots.\textsuperscript{68}

A further aim was to estimate the average values of the measurements of all the variables and respective differences:
1. between eyes of NTG patients and healthy subjects, at T\textsubscript{0} and T\textsubscript{12};
2. between T\textsubscript{12} and T\textsubscript{0} for each of the two groups.

To such end, the standard statistical methods based on the assumption of independent and identically distributed (i.i.d.) observations were not adequate. In fact, the i.i.d. assumption was violated by the presence of both repeated measurements for each eye and the correlation between measurements of fellow eyes. Therefore, the estimates were obtained by mixed effects ANOVA methods.\textsuperscript{69} In each ANOVA model:
1. each variable was included as a response variable;
2. the time of measurement (start of study; 12 months later) and group (NTG; healthy) were included as categorical predictors, with both simple effects and interaction effect;
3. to account for the above-mentioned sources of correlation, two random effects, corresponding to subjects and eyes, respectively, were also included.

The results were reported in terms of estimated averages with respective 95\% CI. The CI for the four differences indicated above were corrected with the Bonferroni rule.

The statistical analysis was performed using the \textit{R} software\textsuperscript{70} with additional \textit{nlme}\textsuperscript{71} and \textit{multcomp}\textsuperscript{72} packages.

---

**Principal component analysis: brief methodological notes**

PCA belongs to a wide class of statistical analyses targeted at describing the main features of the distribution of a large set of inter-related variables by reducing the dimensionality of the data. In PCA, this reduction is achieved by transforming the variables into a new set of variables, called principal components, which are ordered in such a way that the first few — most frequently the first one or two — retain most of the variation present in all the original variables. Thus, the principal components may synthesize the main patterns of correlation among the original variables (as measured by the linear correlation coefficient, Pearson's \( r \)) and, according to such patterns, identify groups (clusters) of subjects provided of the homogeneous features of the original variables.

PCA techniques allow to plot all the original variables and/or individuals within a few plots, thus giving a straightforward visual representation of the features under examination. Usually, variables are represented by vectors, and individuals by points. The interpretation of the plots follows conventional rules.
3. Results

Means and standard deviations of the variables of interest are reported in Table 1. In the multivariate analysis, no complex, *i.e.*, non-linear relationship emerged from the examination of correlation coefficients and scatterplots. In the first PCA (electrophysiological characteristics), according to the scree-plot the first principal component provides an adequate synthesis of the variables under examination. The proportion of total variability of data explained by the first principal component is 48.6%. The patterns emerging from the biplot (Fig. 1a) are quite clear:

1. A global positive correlation emerged among measurements of P100 VEP and P50 PERG amplitudes at T₀ (the vectors corresponding to such variables are overall directed toward the same direction) of moderate or moderate/high amount. In agreement with this, the values of Pearson’s index of correlation (Pearson’s *r*) vary from 0.46 to 0.88.

2. Similarly, a positive correlation emerged among latency measurements at T₀, more pronounced between the two measurements of the P100 VEP wave (*r* = 0.83), whereas the correlation of the latency of the P50 PERG wave with 30-minutes checkerboard pattern (P50/30’) with the other variables is low (*r* ranging from 0.13 to 0.23) (the angles between the vector corresponding to P50/30’ and the vectors representing the other variables are overall nearly 90°).

Based on the relative positions among such elements:

1. For each couple of variables: if the corresponding vectors point in the same direction (the angle is close to 0 degrees), the variables are positively correlated. If two vectors point in opposite directions (the angle is close to 180 degrees), the variables are negatively correlated. If two vectors are orthogonal (the angle is close to 90 degrees), there is a low correlation between the variables.

2. For each couple of individuals, the distance between the corresponding points indicates their similarity: a short distance indicates individuals with comparable values of the original variables, whereas a long distance indicates ‘heterogeneous’ individuals.

3. For each point (individual), the patterns of the original variable are derived by projecting the point onto the vectors. Considering each vector as an axis, the distances between the origin and the projections of the points indicate the magnitude of the corresponding variables.

For further details, see the cited monography by Jolliffe.⁶⁷
Table 1. Descriptive synthesis of diagnostic parameters

Data were reported as mean and standard deviations. NTG = eyes of patients with suspected normal tension glaucoma; Healthy = eyes of healthy subjects. Electrophysiological parameters: L100 and L50 = latency of P100 VEP and P50 PERG waves, respectively; A100 and A50 = amplitude of P100 VEP and P50N95 complex PERG waves, respectively. Text: /15’ and /30’ indicate measurements taken with 15-minutes and 30-minutes checkerboard pattern stimulus, respectively. Visual field indices: MD = mean defect; CLV = correct loss variance. Morphometric parameters: RNFL = RNFL thickness; Lin.C/D = linear C/D. IOP = intraocular pressure. PAC = pachimetry.

3. Furthermore, a global negative correlation emerged between amplitude measurements on one side, and latency measurements on the other, except for P50/30’ PERG latency (vectors corresponding to amplitudes and latencies, respectively, point toward opposite directions). In this case, the values of Pearson’s r vary from -0.58 to -0.18.

In Figure 1a, the points representing the eyes of NTG patients and healthy subjects show a considerable degree of separation. The latter ones (healthy subjects) are characterized by higher values of P100 VEP and P50N95 complex PERG amplitudes, and lower values of P100 VEP and P50 PERG latencies (overall, they stand on the right side of the figure), while the former (NTG) show just the opposite pattern (standing on the left side of the figure).

The measurements at T_{12} showed similar patterns of correlation (Fig. 1b) as those previously illustrated: that is, a positive correlation among amplitude measurements, most pronounced between the P100 VEP waves (P100/30’ and P100/15’); a positive correlation among latency measurements, also most pronounced between the P100 VEP waves; and a negative correlation among latency and amplitude measurements (same as before). No other relevant relationships between variables emerged.

In the second PCA, according to the scree-plot three principal components were retained, with proportions of explained variability of data equal to 30.1%, 27.5%, and 21.5%, respectively. Given that a sound clinical interpretation was provided

Electrophysiological evaluation in normal-tension glaucoma suspects

**Fig. 1.** Principal components of electrophysiological measurements
(a) Principal component biplot. Vectors represent the active variables: P100 VEP latencies and amplitudes at T₀, with 15-minutes and 30-minutes checkerboard pattern stimulus (L100/15', L100/30', A100/15', A100/30', respectively); P50 PERG latencies and amplitudes at T₀ (L50/15', L50/30', A50/15', A50/30'). Dots represent eyes of NTG patients; triangles represent eyes of healthy subjects. (b) Variables map, with active variables (gray) and passive variables (black). The passive variables were P100 VEP and P50 PERG latencies and amplitudes at T₁₂ (labels: same as above).

**Fig. 2.** Principal components of other diagnostic parameters
(a) Principal component biplot. Vectors represent the active variables: Linear C/D (lin.C/D), RNFL thickness (RNFL), mean defect (MD), correct loss variance (CLV), intraocular pressure (IOP), pachimetry (PAC); Dots represent eyes of NTG patients; triangles represent eyes of healthy subjects. (b) Variables map, with active variables (gray) and passive variables (black). The passive variables were measurements at T₁₂ of the variables above, except pachimetry.
Table 2. Estimated average values and differences of diagnostic parameters

NTG = eyes of patients with suspected normal tension glaucoma; Healthy = eyes of healthy subjects. Electrophysiological parameters: L100 and L50 = latency of P100 VEP and P50 PERG waves, respectively; A100 and A50 = amplitude of P100 VEP and P50N95 complex PERG waves, respectively. The text: '/15' and '/30' indicate measurements taken with 15-minutes and 30-minutes checkerboard pattern stimulus, respectively. Visual field indices: MD = mean defect; CLV = correct loss variance. Morphometric parameters: RNFL = RNFL thickness; Lin.C/D = linear C/D. IOP = intraocular pressure. PAC = pachimetry.

only for the first two components, the third one was excluded from the analysis. From the configuration of the vectors in Figure 2a, two major features emerge: a positive correlation between visual field defects (correlation between MD and CLV: \( r = 0.67 \)) and a negative correlation between morphometric parameters (correlation between RNFL and lin C/D: \( r = -0.43 \)).

In Figure 2a, the eyes of NTG patients and healthy subjects show a considerable degree of separation. The former are characterized by higher values of MD and CLV at \( T_0 \) (since overall they stand in the same direction of the MD and CLV vectors), while the latter are characterized by lower values of the same variables. The measurements at \( T_{12} \) show, overall, similar patterns of correlation (Fig. 2b).

The estimates of the average values and differences are reported in Table 2. The average differences between eyes of NTG patients and healthy subjects of P100/15’ VEP latencies are: 12.9 msec (95% CI: (5.5, 20.2) msec) at \( T_0 \), and 10.5 msec (95% CI: (3.2, 17.8) msec) at \( T_{12} \), suggesting that the average values in the first group (NTG) were higher. Smaller differences, also indicating a higher positive difference between the two groups, emerged for P100/30’ latencies: 8.9 msec (95% CI: (2.6, 15.1) msec) at \( T_0 \), and 8.8 msec (95% CI: (2.5, 15.0) msec) at \( T_{12} \). For amplitude measurements, lower average values for the NTG group emerged, at \( T_0 \) and \( T_{12} \), both for the P100 VEP wave and P50N95 complex PERG amplitudes. For example, the estimated differences at \( T_0 \) are: -6.4 µV (95% CI: (-9.8, -3.0) µV) for P100/15’ VEP amplitude and -0.9 µV (95% CI: (-1.4, -0.4) µV) for P50/15’ PERG amplitude. Furthermore, for P50 PERG amplitude, the average differences between \( T_{12} \) and \( T_0 \) in the NTG group are: 0.3 µV (95% CI: (0.1,
0.6) µV) for the P50/15’ amplitude and 0.5 µV (95% CI: (0.2, 0.8) µV) for the P50/30’ amplitude. Such values suggest an increase in amplitude after therapy (T12), whereas no variation in time emerged from the remaining estimates for other electrophysiological measurements. For CRT, positive differences, indicating higher values in the NTG group, emerged both at T0 and T12.

Concerning the visual field indices: for MD, a positive average difference between NTG and healthy subjects emerged at T0: 1.7 dB (95% CI: (0.5, 3.0) dB), indicating that the average value in the NTG group was higher. Also, a positive difference between the groups is shown for CLV at T12: 2.8 dB (95% CI: (0.6, 4.9) dB). For IOP, at T0 no relevant difference emerged between NTG and healthy subjects; subsequently, the average difference between T12 and T0 indicated a reduction of IOP in the NTG group only: -5.2 mmHg (95% CI: (-5.9, 4.4) mmHg). In agreement with this result, at T12 a negative difference between NTG and healthy subjects was found: -5.2 mmHg (95% CI: (-5.9, -4.4) mmHg). No sensible difference emerged for the remaining variables.

4. Discussion

The most important problem for the correct therapy of glaucoma is early diagnosis. The current opinion is that structural changes of the optic nerve fiber layer precede functional changes measured by automated perimetry. However, sometimes a manifest optic nerve cupping is not correlated with visual defects, casting doubt as to whether these patients really have glaucomatous disease that can be prevented by therapy. In this respect, intraocular asymmetry of optic disk size can aid diagnosis. Praecox diagnosis is more difficult in NTG because IOP values are apparently normal, even if larger disks seem to be more susceptible to IOP-related stress because eyes with NTG have a significantly thinner lamina cribrosa and therefore undergo significant displacement due to IOP according to mathematical finite element modeling. Neuroretinal rim loss occurs before visual field loss, but there is a linear relationship comparing 1/lambert differential light threshold (not logarithmic (decibel) scaling) in visual field and temporal rim area.

Among diagnostic exams, electrophysiological tests, such as VEPs and PERG, can be used to quantify RGC function. Retinal ganglion cells undergo a prolonged period of dysfunction and degeneration before cell loss. In fact, many authors have found impaired RGC function by means of electrophysiological measurement in both experimental and human glaucoma studies in subjects with OHT and early POAG with no or minimal visual field defects. In NTG there has been only one electrophysiological study: Lestak found a remarkable P100 amplitude reduction while PERG was almost unaffected.

Likewise, some authors indicate that abnormal PERG recorded in eyes with early stages of glaucoma may often improve after IOP reduction. Therefore, this dysfunction may be partially restored after IOP reduction not only in OHT, but
also in glaucoma patients, as well as in NTG. In the case of NTG, improvement is seen even after smaller IOP reductions because NTG eyes have a lower functional threshold. However, in patients with advanced glaucoma PERG improvement is only slight given that the amount of RGC loss is greater, limiting functional recovery.

In our study of NTG suspects, P100 amplitude VEPs was reduced and P100 latency was slightly delayed. After IOP reduction, these parameters did not show significant modification: this is understandable, as topical therapy is unlikely to have an effect on the functionality (strictly neurological) of the visual pathways. In addition, P50N95 complex amplitude was found to be lower in the NTG group than in the control group.

IOP decreased significantly after therapy, even if the baseline IOP was slightly higher than 15.5 mmHg, demonstrating that these patients had, in fact, NTG, as explained above. Otherwise, P50N95 complex amplitude rose slightly; this is correlated to IOP lowering, also for slight values. There is no inverse correlation between the amount of P50 amplitude increase and IOP reduction.

IOP reduction is correlated to the effective presence of glaucoma; in fact, IOP reduction in normal eyes does not modify P50N95 complex amplitude at all. Therefore, an increase in P50N95 complex PERG amplitude following a decrease in IOP is suggestive of dysfunction in suspected glaucoma (in this study, NTG); this dysfunction could be partially restored after hypotonizing.

Morphometric parameters, i.e., RNFL and linear C/D showed no modification in the NTG suspect group one year after hypotonizing therapy, and neither did visual field indices (MD and CLV). If there is only RGC dysfunction, it is unlikely that optic nerve head changes would be apparent. In this sense, electrophysiological tests could provide a more sensitive measure of RGC integrity.

This pilot study is the first to attempt to differentiate between normal patients with apparent larger disc cupping and NTG suspects with quite normal visual fields. This diagnostic approach may provide important information to avoid starting useless therapy, or, on the contrary, to start precociously hypotonizing therapy in NTG suspects before visual field loss occurs.

Finally, electrophysiological tests could also be used in a similar fashion to the visual field test, but with greater sensibility, allowing ophthalmologists to monitor personalized therapy and even change its course by providing functional information. Furthermore, these tests may provide an objective and indisputable assessment of the effectiveness of neuroprotective therapies.
